A Polymorphism in the Protease-Like Domain of Apolipoprotein(a) Is Associated With Severe Coronary Artery Disease

May M. Luke, John P. Kane, Dongming M. Liu, Charles M. Rowland, Dov Shiffman, June Cassano, Joseph J. Catanese, Clive R. Pullinger, Diane U. Leong, Andre R. Arellano, Carmon H. Tong, Irina Movsesyan, Josephina Naya-Vigne, Curtis Noordhof, Nicole T. Feric, Mary J. Malloy, Eric J. Topol, Marlys L. Koschinsky, James J. Devlin, Stephen G. Ellis

Objectives—The purpose of this study was to identify genetic variants associated with severe coronary artery disease (CAD).

Methods and Results:—We used 3 case-control studies of white subjects whose severity of CAD was assessed by angiography. The first 2 studies were used to generate hypotheses that were then tested in the third study. We tested 12 077 putative functional single nucleotide polymorphisms (SNPs) in Study 1 (781 cases, 603 controls) and identified 302 SNPs nominally associated with severe CAD. Testing these 302 SNPs in Study 2 (471 cases, 298 controls), we found 5 (in LPA, CALMI, HAPI, AP3BI, and ABCG2) were nominally associated with severe CAD and had the same risk alleles in both studies. We then tested these 5 SNPs in Study 3 (554 cases, 373 controls). We found 1 SNP that was associated with severe CAD: LPA 14399M (rs3798220). LPA encodes apolipoprotein(a), a component of lipoprotein(a). 14399M is located in the protease-like domain of apolipoprotein(a). Compared with noncarriers, carriers of the 4399M risk allele (2.7% of controls) had an adjusted odds ratio for severe CAD of 3.14 (confidence interval 1.51 to 6.56), and had 5-fold higher median plasma lipoprotein(a) levels (P=0.003).

Conclusions—The LPA I4399M SNP is associated with severe CAD and plasma lipoprotein(a) levels. (Arterioscler Thromb Vasc Biol. 2007;27:2030-2036.)

Key Words: coronary arteriosclerosis ■ genetics ■ single nucleotide polymorphism ■ lipoprotein(a) ■ risk factors

Severe coronary artery disease (CAD), characterized by occlusive opicardial coronary stenosis, and its consequences such as myocardial infarction (MI) are the leading causes of death in the United States.1 Several major risk factors for coronary disease are well established and form the basis of current risk assessment algorithms.²³ However, some risk factors for coronary disease have not yet been identified, because some of the patients with coronary disease do not have traditional risk factors,4 and traditional risk factors do not reliably predict premature M1.3 The unidentified risk factors probably include genetic variants because genetics is considered to have an important role in coronary disease,6,7 and a family history of cardiovascular disease is an independent risk factor.6 One approach to identify genetic variants associated with complex diseases, such as coronary disease, is to use multiple association studies. We have previously identified genetic variants associated with MI and early-onset.

MI by testing thousands of putative functional SNPs in 3 case-control studies. Thus, we have taken the same approach for angiographically defined severe CAD in 3 case-control studies, and asked if we could identify genetic variants associated with severe CAD.

Methods

Study Design

Because testing 12 077 SNPs for association with severe CAD could result in false-positives, we used 3 consecutive case-control studies. We generated a limited number of hypotheses in the first 2 studies by identifying a subset of SNPs that were nominally associated with severe CAD and had the same risk alleles in both studies and then tested these hypotheses in a third study.

Angiographic Assessment of CAD Severity

The severity of CAD was assessed by scoring the angiograms of subjects who had undergone clinically indicated coronary angiogra-

Data presented as median (Interquartile range) for standard score, mean i standard deviation for Age and BMI, or No. (%) of subjects for the other characteristics. N/A indicates that P values were not calculated because the characteristic was considered during the selection of cases and controls. P values are from Fisher exact test, except those for BMI, which are from the Wilcoxon rank sum test. BMI indicates body mass Index.

phy. The severity of CAD was defined by a stenosis score calculated as the sum of the maximum percent stenosis in 10 coronary artery segments: the left main and 3 segments (proximal, medial, distal), each of the left anterior descending, left circumflex, and right coronary arteries. Details of the angiographic assessment of CAD and scoring methods used in these studies are described in the supplemental Methods (available online at http://uvb.uhujournats.org).

Study Subjects

Subjects in all 3 studies were unrelated women and men who had undergone coronary angiography (characteristics of cases and controls are presented in Table 1). Three goals of our study design influenced the choice of the stenosis score limits and the age limits used to select cases and controls. The first goal was to compare cases and controls at the extreme ends of the stenosis phenotype; the second goal was to include a large number of subjects; and the third goal was to select case and control groups that were about 40% or more female. Because males generally have higher stenosis score than females and have severe CAD at younger ages than females, we set stenosis score limits and age limits separately for males and females. Details of inclusion and exclusion criteria as well as stenosis score limits and age fimits are described in supplemental Methods.

Subjects in Study I and Study 3 were drawn from the Cleveland Clinic Foundation (CCF) Genebank and included only those who selected Eastern European, Northern European, or "Caucasian Other" as the othnicity for both parents. Study I comprised 781 cases and 603 controls selected from angiography patients enrolled in the CCF Genebank between December 2000 and March 2003 and whose DNA samples arrived at Celera before October 2003. Study 3 comprised 554 cases and 373 controls enrolled in the CCF Genebank between July 2001 and December 2003 and whose DNA samples arrived at Celera after August 2004. Subjects in Study 2 were drawn from Genomic Resource at University of California San Francisco (UCSF) and included those who selected only white as their ethnicity. Study 2 comprised 471 cases and 298 controls drawn from angiography patients enrolled between June 1990 and March 2003.

An additional group of 485 subjects who were not in Study 1, Study 2, or Study 3 were used to investigate the association between genotype and Lp(a) levels. These subjects had Lp(a) levels available in the database of the UCSF Genomic Resource and were drawn from the subjects of a previously published genetic study of M1. The clinical characteristics of these 485 subjects are presented in supplemental Table I. Most of the Study I subjects (444 cases with a history of M1 and 602 controls) and more than half (486 of 769) of

Study 2 subjects, but none of the Study 3 subjects, were also subjects in the previously published genetic study of ML^9

To: 815712738300

All subjects gave informed consent and completed an Institutional Review Board approved questionnaire.

SNPs Tested

We tested 12 077 SNPs in Smdy 1. These putative functional SNPs are in 7439 genes, and 70% of the SNPs modify the amino acid sequence of the encoded proteins; the rest are potential regulatory SNPs (3'or 5' untranslated regions, transcription factor binding sites, or exon splice sites). Additional SNPs in the LPA gene were selected using Tagger¹⁰ as implemented in Haploview.¹¹

Genotyping and Laboratory Measurements

Genotypes for individual DNA samples were determined by real-time kinetic polymerase chain reaction (PCR) as described previously. Allele frequencies of SNPs were determined in Shidy I and Study 2 using pooled DNA samples as previously described. The plasma Lp(a) levels in units of mod/l, were determined by an ELISA method as previously described. The size of apo(a) isoforms, reported as the number of KIV repeats in apo(a), was determined by immunoblotting as previously described. Further details of these methods are described in supplemental Methods.

Statistical Analysis

Subject characteristics were summarized by disease status for each study, and differences were assessed using Pisher exact test or the Wilcoxon rank sum test for discrete and continuous characteristics, respectively. A chi-square test was used to assess allele frequency differences that were based on data from pooled DNA samples, and Fisher exact test was used to assess allele frequency differences that were based on genotyping results. An exact test was used to assess deviation of genotype frequencies from Hardy-Weinberg expectutions.14 When logistic regression was used to estimate odds ratios, significance was assessed using the Wald test. When risk utleles for severe CAD were prespecified based on Study I results for SNPs, the association of risk alleles with severe CAD was assessed in subsequent studies using 1-sided probability values and 90% confidence intervals (because there was 95% confidence that the true risk estimates were greater than the lower bounds of the 90% confidence intervals). All other probability values are 2-sided and 95% confidence intervals are presented. Likelihood ratio tests were used to evaluate potential interactions between genotype and each traditional risk factor in separate regression models that included an interaction term between genotype and the covariate of interest. The association

^{*}Calculation of the stenosis score is presented in supplemental Methods.

Figure 1. Association of the LPA I4399M SNP with apo(a) isoform size. Plasma-apo(a) isoform sizes were determined for 114 noncarriers and 35 carriers of LPA 1399M in Study 2. Carriers of the 4399M risk allele had significantly smaller apo(a) isoforms. Individual apo(a) isoform sizes (indicated by Δ) are reported as the number of KIV repeats in the apo(a) isoform, and the median sizes are indicated by the dashed lines.

of LPA I4399M genotype with apo(a) isoform size (Figure 1) and untransformed Lp(a) plasma levels (Figure 2) were assessed with the Wilcoxon rank sum test. A multiple linear regression model was used to estimate the relationship between the *LPA* I4399M carrier status and the In of Lp(a) plasma levels while adjusting for the effect of apo(a) isoform size. The in transformed Lp(a) levels were used in the linear regression analysis so that the distribution of the residuals more closely approximated a Gaussian distribution.

Results

LPA 14399M Is Associated With Severe CAD

The demographic and clinical characteristics of the subjects of Study 1, Study 2 and Study 3 are summarized in Table 1.

We measured the allele frequencies of 12 077 putative functional SNPs in Study 1 cases and controls using pooled DNA samples and identified 302 SNPs that were nominally associated with severe CAD (P<0.05) and had odds ratios for severe CAD of greater than 1.3 and had minor allele frequency estimates that were greater than 2% (supplemental Table II). For these 302 SNPs, we determined allele frequencies in Study 2 cases and controls using pooled DNA samples and asked if the risk allele identified in Study 1 was also associated with severe CAD in Study 2. For SNPs that were associated with severe CAD and had the same risk alleles in both pooling studies, we then confirmed their allele frequencies by genotyping individual DNA samples from Study 1 and Study 2 subjects. We found that the risk alleles of 5 SNPs in 5 genes were nominally associated (P<0.05) with severe CAD in both studies (Table 2). The genes encoded apolipoprotein(a) (encoded by LPA), calmodulin 1 (CALMI), huntingtin-associated protein 1 (HAP1), adaptor-related protein complex 3, β -1 subunit ($\Lambda P3B1$), and ATP-binding cassette, subfamily G, member 2 (ABCG2). The genotype distributions of these 5 SNPs in the control groups of Study I and Study 2 did not deviate from Hardy-Weinberg equilibnum expectations (P > 0.05).

Figure 2. Association of the LPA I4399M SNP with plasma Lp(a) levels. In 161 Study 2 subjects for whom plasma Lp(a) levels were available, carriers of the LPA 4399M allele (n=12) had higher Lp(a) levels then did noncarriers (n=149). In an additional 485 subjects for whom plasma Lp(a) levels were available, carriers of the LPA 4399M allele (n=21) also had higher Lp(a) levels than did noncarriers (n=464). The median values are shown and to the boxes and indicated by the horizontal lines inside the boxes. The boxes extend from the 25th to 75th percentile and the whiskers extend from the lowest to the highest value.

After prespecifying the risk alleles based on Study 1 and Study 2 results, we tested the hypotheses that the risk alleles of these 5 SNPs would be associated with severe CAD in Study 3. We found that the risk allele of 1 of the 5 SNPs, I4399M (rs3798220) in the LPA gene, was associated (P<:0.05) with severe CAD. The LPA gene encodes apolipoprotein(a) (apo(a)), which is a component of lipoprotein(a) (Lp(a)), and the 14399M SNP is located in the protease-like domain of apo(a). Carriers of the 4399M allele constituted 2.7% of controls and 5.2% of cases in Study 3. Compared with noncarriers, carriers of the 4399M risk allele had an odds ratio for severe CAD of 3.14 (CI 1.51 to 6.56, P=0.005, Table 3) after adjusting for traditional risk factors (age, sex, smoking, hypertension, diabetes, dyslipidemia, and body mass index [BMI]). This association remained significant (P=0.026) after Bonferroni¹⁵ correction for testing 5 SNPs in Study 3. We observed no indication of an interaction between the 14399M genotype and age, sex, smoking, diabetes, dyslipidemia, or BMI in Study 3 (P>0.11), but we did observe an interaction between genotype and hypertension (P=0.02). However, when we tested for interaction between 14399M genotype and hypertension in Study 1 and Study 2 we did not observe significant interactions (I=0.94 and P=0.78, respectively).

Genetic Variants in Linkage Disequilibrium With LPA 14399M

We used 2 approaches to investigate whether the association of LPA 14399M with severe CAD could be due to linkage disequilibrium (LD) between 14399M and other variants in the LPA gene. In the first approach, we asked whether other SNPs in the LPA gene were associated with severe CAD and

could explain the association of I4399M with severe CAD. The HapMap project reports 65 SNPs in the LPA gene that have allele frequencies >2% in the CEU population (Utah residents with ancestry from northern and western Europe, HupMap public release #2116). We identified a set of 18 SNPs that tagged 50 of these 65 SNPs with an $r^2 > 0.80$, 12 SNPs with an $r^2 < 0.8$ but >0.5, and 3 SNPs with an $r^2 < 0.5$. We then genotyped the subjects of Study 1 (the largest of the 3 studies) for these 18 SNPs and the I4399M SNP which tags only itself. Except for the I4399M SNP, none of these 18 additional tagging SNPs was associated with severe CAD after adjusting for traditional risk factors (supplemental Table III). In Study 1 the I4399M SNP is not in strong LD with any of the other 18 tagging SNPs ($r^2 \leq 0.1$), and the HapMap project does not report LD for the LPA 14399M SNP because that position is not polymorphic in the 30 CEU trios (60 parents and 30 offspring) genotyped by the HapMap project.

We also investigated whether the association of the *I.PA* I4399M SNP with severe CAD could be attributable to LD between I4399M and the repeat polymorphism in the LPA gene that encodes the kringle IV (KIV) repeat length variation. This variation determines apo(a) isoform size which has been previously shown to be associated with coronary disease. Direct determination of KIV repeat length in the *LPA*

gene requires nucleated cells which were not available for these studies.18 However, the KIV repeat length can also be determined from the number of KIV repeats in the apo(a) isoforms present in stored plasma.19 Because stored plasma was available for some of the Study 2 subjects, we calculated the number of subjects needed to have 80% power to detect an association between the I4399M SNP and apo(a) isoform size (supplemental Methods). We then determined apo(a) isoform size for 35 carriers and 114 noncarriers of 4399M among Study 2 subjects. We found that in this group of 149 subjects, the I4399M SNP genotype was associated with apo(a) isoform size: the median apo(a) isoform size in curriers contained 17 KIV repeats and in noncarriers, 22 KIV repeats (P<0.001, Figure 1). However, in this group of 149 subjects, the association of the LPA 4399M allele with severe CAD remained significant after adjusting for the apo(a) size (odds ratio=4.36, CI 1.53 to 12.4, P=0.006; supplemental Table IV). Thus, we found no evidence that the association between the LPA 4399M allele with CAD is explained by apo(a) size polymorphism.

Plausibility of the Association of LPA I4399M With Severe CAD

To investigate the biological plausibility of the association between the LPA I4399M SNP and severe CAD, we asked

whether the SNP was associated with plasma levels of Lp(a), which have been associated with coronary disease.20 Plasma Lp(a) levels were available in the UCSF Genomic Resource database for 161 subjects of Study 2 (these 161 subjects included 122 of the subjects shown in Figure 1; plasma Lp(a) levels were not available for Study 1 or Study 3 subjects). In these 161 subjects of Study 2, we found that Lp(a) levels were higher in carriers of the 4399M allele than in noncarriers (P-0.002): median levels were 356 nmol/L and 52 nmol/L, respectively (Figure 2). To confirm this result, we tested the association of the I4399M SNP with Lp(a) levels in 485 additional subjects with available Lp(a) levels (characteristics of these subjects are presented in supplemental Table I). These 485 subjects had not been included in Study 1, Study 2, or Study 3. In these 485 additional subjects, we again found that the Lp(a) levels were higher in carriers of the 4399M allele than in noncarriers (P=0.003, Figure 2).

We also asked whether the association of I4399M with Lp(a) levels can be explained by the association of I4399M with apo(a) size. Of the 161 Study 2 subjects who had Lp(a) levels available (left panel of Figure 2), 122 also had apo(a) size information available from the analysis in Figure 1. In these 122 subjects, we found that Lp(a) levels were 5.9-fold higher in carriers of the 4399M allele than in noncarriers, corresponding to a 1.78-In unit increase in Lp(a) levels (P=0.002; supplemental Table V), and after adjusting for apo(a) size, Lp(a) levels remained 3.7-fold higher in carriers than in noncarriers, corresponding to a 1.32-In unit increase in Lp(a) levels (P=0.013; supplemental Table V).

Discussion

We found that a genetic variant of LPA, the I4399M SNP, is associated with severe CAD. Carriers of the 4399M risk allele constituted 2.7% of the control subjects and had an adjusted odds ratio for severe CAD of 3.14 (90% CI 1.51 to 6.56; Table 3). This association seems unlikely to be a false-positive finding because it remained significant after correcting for multiple testing.

The LPA gene encodes the apo(a) protein of the Lp(a) particle, and high plasma Lp(a) levels are considered an emerging lipid risk factor for cardiovascular disease.3.21 The variability in plasma Lp(a) levels among individuals are largely determined by genetic variations at the LPA gene locus,72 a fraction of that variability has been attributed to variation in apo(a) size22,23 resulting from the KIV type-2 repeat polymorphism.19 The apo(a) protein in apparently healthy European Caucasians has been previously reported to contain a median of 27 KIV repeats.24 The somewhat lower number of KIV repeats we observed in noncarriers (22 repeats) may reflect the higher than normal risk status of the subjects of our studies: all underwent clinically indicated coronary angiography. A number of other polymorphisms in the kringle region and in the 5' noncoding region have also heen reported to be associated with Lp(a) levels.23.25-30

We did not find evidence that the association of *LPA* I4399M with severe CAD was attributable to other variants in the *LPA* gene. We investigated 18 additional SNPs in the *LPA* gene that tagged 50 of the 65 SNPs that have allele frequency >2% in the HapMap CEU population. These 18 SNPs

included 2 SNPs, T3907P and L3866V (same as T3888P and L3847V in Chretien et al), which have recently been reported to be associated with Lp(a) levels.³⁰ We found that none of these 18 SNPs could explain the association of LPA I4399M SNP with severe CAD. We also found that the apo(a) isoform size did not explain the association of LPA I4399M SNP with severe CAD.

Although we tested 12 077 putative functional SNPs from more than 7000 genes, the one genetic variant that remained associated with severe CAD in all 3 studies was the I4399M SNP in LPA, a gene that has often been implicated in vascular disease.21 Thus, the association of LPA I4399M with severe CAD is biologically plausible both because LPA is a candidate gene for cardiovascular disease and also because this SNP is associated with Lp(a) levels (Figure 2). Whether or how the isoleucine to methionine substitution directly affects Lp(a) levels or CAD risk is not known. It is interesting to note that in apolipoprotein A-I, the oxidation of methionine residues has been shown to alter the sites and rates of the protoolytic cleavage of apolipoprotein A-I.31 Thus we could speculate that potential oxidation of the 4399 methionine residue could alter apo(a) and Lp(a) catabolism, eg, by altering proteolytic fragmentation of either free or LDLbound apo(a),32 hence altering Lp(u) levels. Alternatively, it has been suggested that Lp(a) plays a role in fibrinolysis21 and that it may be a carrier for proinflammatory and oxidized phospholipids³³; both of these roles could conceivably be affected by a methionine substitution and its potential oxidation in the protease-like domain of apo(a). It would therefore be interesting to investigate the potential role of the 14399M SNP in Lp(a) physiology either in vitro or in transgenic animal models that overexpress the 2 14399M alleles. Nevertheless, given that determining the KIV repeat length in the LPA gene or the apo(a) size in plasma requires more specialized techniques and samples that may not be available, the association of I4399M with apo(a) size could provide an alternative approach for obtaining information related to KIV repeat length or apo(a) size.

Results in this report contain several attributes that are considered desirable for a genetic association study,34 including biological rationale, rigorous phenotyping and genotyping, multiple large sample sets, correction of probability values for multiple testing, and physiologically meaningful supporting evidence. It is worth noting that the I4399M SNP, which we found to be associated with severe CAD as well as with Lp(a) levels, has a relatively low frequency of about 2% in the control group. This finding suggests the need for designing sequencing projects with adequate power to detect SNPs of similar frequency. However, possible limitations include the inability of coronary angiography to identify circumferential disease; thus the stenosis score may have underestimated the extent of CAD for some of the control subjects. In addition, in Study 2 we tested only those SNPs that had had an odds ratio for severe CAD of greater than 1.3 in Study 1. Furthermore, even for SNPs with a true OR of 1.3, we had 80% power to detect association with severe CAD in Study 1 only for SNPs with minor allele frequencies of 0.2 or higher. This combination of a power limitation for low frequency SNPs in Study 1 and the odds-ratio cutoff we used

Luke et al An LPA Protease-Domain Variant Associated With CAD

5107494266

to advance SNPs from Study 1 to Study 2 could have lead to false-negative results. Our analyses of Lp(a) levels and apo(a) size were restricted to those limited to a subset of subjects that had Lp(a) levels in the database and our analyses of apo(a) sizes were restricted to a subset of those subjects for whom plasma samples were in storage, and not all of these subjects had Lp(a) levels available. Apo(a) size determined from stored plasma may not fully reflect the genetic variability of the KIV repeat length polymorphism because larger apo(a) isoforms are secreted into the plasma at lower levels.35 However, we could not directly determine the KIV repeat length in the LPA gene because nucleated cells were required but were not available. Finally, these results were derived from case-control studies of white subjects; thus the association of the LPA I4399M SNP with severe CAD and Lp(a) levels should be investigated in other ethnic groups and in prospective population-based cohorts.

In conclusion, we found that the I4399M genetic variant of LPA is associated with severe CAD, and the association remained significant after adjusting for multiple testing. The plausibility of this association is supported by the association of I4399M with Lp(a) levels. Functional studies of the LPA 4399M variant could shed light on the role of Lp(u) in the pathophysiology of vascular disease.

Acknowledgments

The authors thank Thomas White, John Sninsky, Lance Bare, Olga Takoubova, and Bradford Young for helpful comments, and Judy Lonic, David Ross, Alla Smolgovsky, Juel Bolonick, and Steve Schrodi for data and statistical analyses. The authors are grateful to the subjects of the genetic association studies.

Sources of Funding

This study received funding from the University of California Discovery Grant Program, which is jointly funded by the University of California and the State of California with matching funds from Celera.

Disclosures

M.L., D.M.L., C.R., D.S., J.C., D.U.L., A.A., C.T., and J.D. are current or former employees of Colora, J.K. and M.M. received funding from the University of California Discovery Grant Program which is jointly funded by the University of California and the State of California with matching funds from Celera, S.E. had been a puid consultant of Celera.

Methods

Angiographic Assessment of CAD Severity

The presence of CAD was assessed by performing coronary angiography as clinically indicated with each vessel imaged in multiple views of obliquity, including standardized views. Lesion narrowing was estimated in reference to adjacent angiographically normal appearing segments by highly experienced cardiologists. Since the Cleveland Clinic Foundation Genebank (CCF) and the Genomic Resource at the University of California San Francisco (UCSF) had enrolled subjects independently, the procedures used for recording and scoring coronary stenosis in subjects enrolled by CCF (Study-1 and Study-3) differed from those used at UCSF (Study-2). For subjects in Study-1 and Study-3 drawn from the CCF Genebank, lesions of less than 50% stenosis were coded as "<50%" and were not included in the calculation of the stenosis score so that patients without any lesion of 50% or more stenosis would have stenosis scores of zero. For subjects in Study-2 drawn from the Genomic Resource at UCSF, the procedure for recording and scoring coronary stenosis differed from those used at CCF in two respects. First, the percent stenosis of lesions of 10% or greater stenosis were recorded; second, up to two lesions for each of the ten coronary segments were summed to provide the stenosis score for that segment. Because of these differences in the scoring procedures, the stenosis scores from CCF and UCSF are not directly comparable, and the stenosis score for the UCSF subjects would in general be higher than those for the CCF subjects. However, within each study, the stenosis scores were calculated using the same procedure for all subjects and therefore were comparable between cases and controls within each study.

LPA online supplement

Study Subjects

Three goals of our study design influenced the choice of the stenosis score limits and the age limits used to select cases and controls. The first goal was to compare cases and controls at the extreme ends of the stenosis phenotype, the second goal was to include a large number of subjects, and the third goal was to select case and control groups that were about 40% or more female. Since males generally have higher stenosis score than females and have severe CAD at younger ages than females, we set stenosis score limits and in Study-1 also age limits separately for males and females.

Study-1 comprised 781 cases and 603 controls selected from angiography patients enrolled in the CCF Genebank between December 2000 and March 2003 whose DNA samples arrived at Celera prior to October 2003. Controls were patients with a stenosis score of zero. Since young controls could become cases later in life, we excluded from controls females younger than 42 and males younger than 37 years old, these age cutoffs resulted in a control group that was 38% females. Patients with a history of MI, stroke, aortic aneurysm, aortic dissection, or carotid disease were also excluded from the control group of Study-1. For female cases we included patients with stenosis score greater than 75. For males, we included patients with stenosis score greater than 150. Since genetics plays a diminished role in the disease of older individuals, we excluded females older than 75 and excluded males older than 66 from the case group of Study-1. These age and stenosis score cutoffs resulted in a case group that was 39% female.

RECEIVED CENTRAL FAX CENTER MAY 2.9.2008

LPA online supplement

Study-3 comprised 554 cases and 373 controls enrolled in the CCF Genebank between July 2001 and December 2003 whose DNA samples arrived at Celera after August 2004. Controls had stenosis score of zero and were 46 or older. This age cutoff resulted in a control group that was 56% female. Patients with a history of MI, stroke, aortic aneurysm, aortic dissection, carotid disease, or other peripheral vascular disease were excluded from the control group of Study-3. Female cases had stenosis score of 100 or higher, male cases had stenosis score of 250 of higher. These stenosis score cutoffs resulted in a case group that was 35% female.

Study-2 comprised 471 cases and 298 controls drawn from angiography patients enrolled between June 1990 and March 2003 in the Genomic Resource at UCSF. Since the stenosis score of Study-2 subjects would in general be higher than those of Study-1 and Study-3 subjects due to the different scoring procedure, female controls had stenosis score of 40 or lower and male controls had stenosis score of 100 or lower. These stenosis score cutoffs resulted in a control group that was 44% female. Patients with a history of MI, stroke, or acrtic aneurysm were excluded from the control group of Study-2. Female cases had stenosis score of 200 or higher and male cases had stenosis score of 300 or higher. These stenosis score cutoffs resulted in a case group that was 46% female.

Genotyping and Laboratory Measurements

Genotypes for individual DNA samples were determined by real-time PCR as described previously. 1,2 Primer sequences and cycling conditions are available from the authors upon request. To assess genotyping accuracy, we also determined the genotype of the

LPA online supplement

LPA I4399M SNP for 2,906 subjects using an oligonucleotide ligation assay³ and found > 99.9% concordance between the two methods, which is similar to what we had observed in previously published studies that compared these two genotyping methods.¹ Allele frequencies of SNPs were determined in Study-1 and Study-2 using DNA pools as previously described.^{1,4} Briefly, each pool typically included 50 cases or controls and was made by mixing equal amounts of DNA from each individual member of the pool. Each allele was amplified separately by PCR using pooled DNA samples. The allele frequency for each pool was calculated from amplification curves for each allele. The plasma Lp(a) levels in units of nmol/I were determined by an ELISA method as previously described.5

5107494266

The size of apo(a) isoforms, reported as the number of KIV repeats in apo(a), was determined by immunoblotting as previously described. 6 We attempted to determine the apo(a) isoform size for 155 subjects of Study-2 (39 carriers, 116 noncarriers), and succeeded for 149 subjects (35 carriers, 114 noncarriers). Of the 149, 101 had a single band and 48 had double bands. The mean isoform sizes were used where two isoforms were of equal intensity (6 of the 48 subjects with two bands), otherwise the sizes of the single or of the isoform present in higher level were used (the remaining 143 subjects).

Statistical Analysis

To determine sample size required to provide >80% power to detect an association of apo(a) size variation with the LPA I4399M genotype, we estimated from a previous report the standard deviation in apo(a) size variation to be approximately 5 KIV repeats.

LPA online supplement

Using a more conservative assumption for a standard deviation of 7 KIV repeats, we calculated that a sample size of 50 carriers and 100 noncarriers would provide 90% power to detect differences in mean apo(a) size of 4 or more KIV repeats.

TABLE I (online). Clinical Characteristics of 485 Additional Subjects Enrolled by the UCSF Genomic Resource.

^{*}Odds ratio for each allele was estimated in a model that assumed risk was additive on the log scale.

[†]P values are from Wald test and are 2-sided.

[‡]Based on NCBI Genome Build 36.

[§]Tagging SNPs are designated based on TapMap⁸ using Tagger as implemented in Haploview, ⁹ amino acid positions are based on a published protein sequence. ¹⁰

Adjusted for age, sex, smoking, diabetes, dyslipidemia, hypertension, and BMI.

Bold type indicates the I4399M SNP.

T3907P and T3866V are the same as T3888P and L3847V in Chretien et al. 11, which counts from the first amino acid after the signal peptide.

TABLE IV (online). Association of LPA 14399M and Apo(a) Size With Severe CAD

5107494266

				Unadjuste	d .		Λdjusted	Š
	Case*	Control*	OR	CI;	P value	()R	CI [‡]	P value [‡]
I4399M								
MM+IM	30	5	5.40	1.96 -14.9	0.001	4.36	1,53-12.4	0.006
11	60	54	1.00	reference		1.00	reference	
apo(a) [†]								
KIV	90	59	0.90	0.83-0.97	0.008	0.93	0.86-1.01	0.090

Analysis of Study-2 cases and controls with apo(a) size information available, n = 149.

[†]The apo(a) size was coded as an ordinal variable corresponding to the number of KIV repeats, where the odds ratio for severe CAD for apo(a) was calculated to estimate the risk associated with each additional KIV repeat.

[‡]P values are two-sided and 95% CI are presented. P values were by Wald test.

In the models that estimated adjusted odds ratios for severe CAD, the risk associated with 4399M was adjusted for apo(a) size, the number of KIV repeats, and the risk associated with apo(a) size was adjusted for 4399M carrier status.

HECEIVED CENTRAL FAX CENTER MAY 2 9, 2008

TABLE V (online). Association of LPA 14399M and Apo(a) Size With the Natural Log of Plasma Lp(a) Levels

Variable	coefficient	95% CI	P value
I4399M	,		
Intercept	3.93	3.64-4.22	< 0.001
MM+IM	1.78	0.65-2.90	0.002
apo(a) size			
Intercept	7.45	6.22-8.68	< 0.001
KIV repeats	-0.16	-0.22-(-0.10)	< 0.001
14399M and apo(a) size			
Intercept	7.11	5.88-8.35	< 0.001
MM+IM	1,32	0.28-2.35	0.013
KIV repeats	-0.15	-0.21-(-0.09)	< 0.001

Study-2 subjects with Lp(a) level and apo(a) size available, n = 122. The coefficients were estimated by linear regression. The coefficients indicate the change in the mean natural log of Lp(a) level per unit increase in the variable. The 14399M variable was coded 1 for carriers and 0 for noncarriers. The apo(a) size variable was the number of KIV repeats. P values were calculated with an F test.
